Randolph Bentson

Technical Report CS-93-126

October 16, 1993

#### Abstract

In [Ric80], John Rice proposed a list of sixteen problems to be used to test the expressive power and performance of languages in parallel computational environments. Since then, there have been several followup reports. One from Purdue, [MR87], examines the Fortran extensions on various architectures. Two CSU reports, [HHRO88] and [AHO90], have looked at the language SISAL. A recent report from Purdue, [RJ90], adds a seventeenth problem to the set.

This report takes up the challenge by looking at how well an implementation of Backus' FP, TFP [Ben92], can express a solution and how quickly that solution can be computed. Because of the fine-grain parallelism available in the graph reduction method used by TFP, dramatic parallelism is available for complex programs. Modest sized problems, such as computing polynomial interpolant values over 32 points (problem 7) saw an average parallelism of over 500 and a peak of ten times that. Simple programs did not fare as well, due mostly to the nearly linear nature of some of the functions and PFOs. Certain functions and PFOs, such as trans, append, and $\backslash /$, carry significant serialization in their implementation, and therefore can slow down programs that use them.

This suggests that the linked-list implementation of sequences can be a handicap for simple programs, but this is masked whenever the program complexity becomes sufficiently large.

## 1 Language Description

The computational model expressed in Fortran is often referred to as von Neuman style. This language style makes explicit references to memory. The state of the computation, as it proceeds, is described in the language as changes in values of variables. It is incumbent upon the programmer and the compiler to access variables in the appropriate sequence. The language forces one to specify the order of operations to a degree far beyond the minimum needed to arrive at a solution. This over-specification actually interferes with attempts by the compiler to discover parallelism. Most will acknowledge that this style of programming makes it difficult to identify the maximum parallelism allowed by the problem.

Languages of this style have been extended to make it easier for the programmer to code a solution and for the compiler to discover parallelism. One common extension is the provision of objects such as vectors and arrays that can be operated on via simple operators. The compiler can then determine the best way to implement such an operator. Another extension is to allow the programmer to specify many distinct tasks which work co-operatively.

Another style of language, called functional or applicative, extended this idea that parallel tasks should be easily derived from the program. In these languages, the tasks are not specified directly by the programmer, but rather are derived directly from the property of the languages that state the order of the evaluation of expressions does not yield different results. The compiler and run-time can then create tasks out of the evaluation of expressions and functions whenever there is benefit in doing so.

SISAL is the result of one of the efforts to expose more parallelism to the compiler without burdening the programmer. It does so, in part, by removing the issue of changing variable values. Value holding identifiers in SISAL have a single value assigned to them. Until that assignment, the value can be thought of as a special value "not yet known". Programs are expressed in terms of expressions built up from functions and identifiers. Additional language constructs support aggregrate operations on arrays, etc. It appears that SISAL is reasonably concise in expression and efficient in execution.

FP is an even more dramatic departure from the von Neuman language style. It is purely functional, with no names other than function names. All functions take a single object as an argument and return a single object as a result. This is not a hardship because an object is an atom or a sequence of atoms and/or sequences, and can describe arbitrarily complex data. In fact, one often speaks of "input values" when one should say "values in the input sequence". Because this mis-statement is understood, it normally goes unremarked. Any expression of state must be explicit, i.e., the state of computation is passed as an argument to a function and the function returns the value of the new state.

FP has several functional forms or program forming operations (PFOs) that are used to combine functions into more complex functions. Unlike functions which operate only on objects, these PFOs operate on functions as well as objects. The standard PFOs are condition, composition,
construction, while-iteration, insertion (a reduction operation), application-to-all, and binding. These are not a minimal orthogonal set, but rather a large, strong set of operations likely to be sufficient to conveniently program any function desired. This is in contrast to many other functional languages which allow the programmer to define new program forming operations. By limiting the program forming operations, it is possible and reasonable to develop an algebra of programs. This enhances the ability to analyze an FP program.

FP was defined as a strict language, where all inputs to functions are evaluated before the function started. In addition, functions (and all PFOs except condition) return a special value, called "bottom", shown as ? on displays or as $\perp$ when typeset, if their input contains bottom or if their results are undefined. The implementation considered in this report is not strict. As a consequence all programs that return a non-bottom result in a strict implementation will return the same non-bottom value in this version, but because a function need not return bottom as its value whenever bottom appears in its input sequence, additional non-bottom results can appear in a program's range.

The difference becomes apparent when one considers the function $1 \circ[f 1, f 2]: \mathrm{x}$. In a strict system, if $\mathrm{f} 2: \mathrm{x}$ returns bottom, then [ $\mathrm{f} 1, \mathrm{f} 2$ ]: x always returns bottom, and then $1: ?$ returns bottom.

If the construction PFO is non-strict, $1 \circ[f 1, f 2]: x$ can have different values under different evaluation schemes. If $f 2: x$ is evaluated early, [f1,f2]: $x$ is evaluated as bottom, and $1: ?$ is then evaluated as bottom. But if composition is applied before $f 2: x$ has been evaluated, the value $f 1: x$ would be selected from the partially evaluated sequence.

The TFP implementation allows function results to be represented by "continuations", or incompletely evaluated function applications. By this method, the composition PFO could return a sequence of continuations and the selection function could be evaluated before it $\mathrm{f} 2: \mathrm{x}$ is evaluated (and its results would therefore be discarded). But if we are to have results that are invariant under execution timing, we must always discard the results of $f 2: \mathrm{x}$, regardless of its status as a continuation or bottom. By this we see that non-strictness is a practical consequence of allowing continuations, and that continuations are a convenient way to develop non-strict implementations.

Lazy evaluation follows the principle that no function is evaluated until its results are needed. In a single processor system this reduces execution time by avoiding unneeded computation (provided the management overhead is small enough). The lazy evaluation of a strict language would save no time because all the parameters would be evaluated; therefore as a practical matter, all languages implemented with lazy evaluation are non-strict. But this does not mean that all non-strict languages use lazy evaluation.

TFP's use of non-strictness offers improved parallelism because operations such as composition and selection can proceed before all of the elements of their input sequence have been evaluated. In addition one can proceed with the parallel evaluation of as-yet-unneeded continuations, even while necessary continuations are being evaluated. This non-strict, not-fully-lazy evaluation scheme is
herein called lenient evaluation.

## 2 Language Idioms

The body of FP code is small. Other functional languages with more conventional syntax are more commonly used. The comments here are based on experiences implementing solutions to the Purdue problem set.

Sometimes a solution was trivially derived from the problem statement. This usually occurred because a PFO captured the essence of the problem. In other cases more effort, such as writing non-trivial functions, was required. It is possible to in-line all non-recursive functions into a single large program. Because of restrictions on the application of higher-order functions on user defined functions, this was a common style in writing APL programs. Fortunately FP has no such restrictions, and because there is no performance cost in using functions, the final program is developed from many smaller functions. As a bonus, this provides for enhanced readability.

In general, one builds an initial value object and then pushes that object through successive functions (using the composition PFO) until a final value object is determined. Sometimes the same function is applied several times, in which case the use of the while-iteration PFO or recursion is appropriate.

Functions can be applied to all elements of the sequence using the aa PFO. This provides significant parallelism, especially when the functions are complex in nature. This leads to the style of moving the data about until one has a sequence of independent datasets that can be operated upon. In Problem 9 the input matrix is moved about until each element is replaced by a sequence containing that element and its neighbors. The averaging function is then applied to each of these sequences.

Often the last function sums the elements of the sequence. The PFOs <br>, /, and $\backslash /$ insert a binary operator such as $\boldsymbol{+}$ or $*$ between terms of the series. Their use acts as a classic reduction operator.

The FP implementation being tested applies functions to objects as soon as the source object is sufficiently defined. In many cases the result object becomes defined in stages. For instance, $\mathrm{f} 1 \circ[\mathrm{f} 2, \mathrm{f} 3]: \mathrm{y}$ has an intermediate object that is known to be a sequence [f2:y,f3:y](f2:y,f3:y), but the values of the elements may not be known. It is possible to apply $f 1$ to this sequence before the values are known and $f 1$ is delayed only as necessary.

Unfortunately this implementation isn't as lenient as it could be. Even if the values of the elements in a sequence may be represented by continuations, the number of elements in a sequence must be known before that sequence is made available as an output. PFOs such as apndl and apndr cannot be used in recursions to provide infinitely long sequences. This implementation restriction prevents one from using streams of unbounded data in programming.

Another shortcoming with this implementation is its failure to recognize common sub-expressions. As a consequence, the programmer is obliged to "hoist" those sub-expressions to outer levels if the extra computation is to be avoided.

## 3 Basis for Timing

This FP implementation is a multi-threaded graph reduction interpreter. The interpreter has been designed with respect to a possible implementation on a shared memory multiprocessor with multiple operations per instruction and low-overhead scheduling primitives, where each processor supports a number of execution threads. Although it is currently executed on a uniprocessor, it simulates parallel performance by way of timing simulated parallel execution. Command line arguments control the number of parallel processors being simulated, as well as the maximum number of threads on each processor.

Each reduction step computes the number of machine ticks that would be required if the reduction had been done on a multiprocessor. This timing information is used to keep track of when the function's results are to be made available for further processing, i.e., when the next function can be applied. Until this delay is satisfied, that function application counts as one of the active threads. When the number of active threads reaches the per-processor limit, additional continuations are placed in a ready queue. When an active thread completes, i.e., when enough time has elapsed so that the results are made available, another continuation thread is removed from the ready queue and is made active. The simulator moves from one simulated processor to the next, extracting threads from ready queues, computing function results, moving the thread to an active queue, advancing the simulated clock, etc. In this way, the system can determine how long the FP program would take to execute on a multiprocessor.

Although the architecture being modeled supports 256 processors $\times 128$ threads/processor, tests can simulate more or fewer processors or threads/processor. In addition to varying the data set size, problems are examined with respect to the maximum number of available processors and threads per processor. In this way we can examine how effectively parallelism can be exploited. One subtle limit to performance is that although one can have many threads on a processor, performance does not increase linearly as threads are added. The first thread on a processor achieves about $1 / 12$ of the processor's capability. This is because no thread may have more than one instruction in the pipeline at any moment. In a very busy system this utilization may be smaller because of memory access delays, but with a good compiler, the effect should be insignificant. As more active threads are added to a processor, utilization and aggregate performance increases until the pipeline is full. Adding more threads beyond this point actually reduces the per-thread performance, but because the thread scheduling is performed by hardware, there is no additional overhead to hurt aggregate performance. This is simulated by applying a slow down factor to all timing. The factor is computed as slow_down = active_tasks < PipeLineSize ? 1.0 : active_tasks / PipeLineSize; where PipeLineSize is normally 12.

Fourteen of the seventeen problems have been programmed in FP. The performance of each program is examined with respect to various data set sizes. The main dependent variable is the number of machine ticks required for solution. Additional dependent variables include the average and maximum number of active tasks, etc. Tests of of increasingly larger data sets shows that for any given data set size, adding processors and threads reduces execution time to a limit. As predicted by Amdahl's Law [Amd67], there is always a threshold below which execution time cannot be reduced, regardless of the available parallel hardware. In "good" parallel programs, the degree of parallelism grows with the problem set size, and the effect of the sequential component is lessened. In "bad" parallel programs, the sequential component grows with the problem set size, or the degree of parallelism does not grow, and thus the sequential component stays visible, or even dominates the computation.

One significant assumption in computing time in the TFP simulator is that the allocation and deallocation of cells (which contain objects and code definitions) takes some small, fixed amount of time. If all threads accessed a common pool of cells, this assumption would not be realistic due to blocking. If a (mostly) non-blocking allocation scheme is used, (such as a pool per processor) this assumption is reasonable.

## 4 Test Methods

Each program is run under the control of a test framework. The outer loop in the framework generally starts at one and doubles the problem set size until limits to parallelism are found, excessive paging occurs on a 16 Mbyte system, or the simulation time becomes unbearable. An inner loop controls the number of processors being simulated and the threads on each. It generally starts at one and doubles until it equals the dataset size or shows the limits to parallelism.

In some cases the program uses the dataset size directly and in other cases the framework generates the test dataset via a test generation program. (And in the case of problem 16, the number of rows and columns is set to $\lg N$.) This dataset is then read as data to the program under test. If the test dataset generation were done within the program under test, the cost of that generation would be charged against the program, confusing performance issues.

The dataset generation is rather naive - the data are not randomly created and only slight effort is put into domain limiting.

The study has been largely restricted to nearly asymptotic performance, i.e., how much parallelism is available given unlimited processors (or at least all the processors in the system). As noted in the Performance sections of many of the problems, the underlying time complexity of any TFP program is $\mathcal{O}(N)$, or at best $\mathcal{O}(\lg N)$, because of limitations in accessing sequence elements. Since this time is masked if the processing of the elements takes long enough, or if the sequences are short enough, the "actual" performance reported is based on inspection of these limited results. This is what is meant by the "nearly asymptotic performance" mentioned earlier.

Another issue is how effectively fewer processors can speed-up the solution. When all goes well, one sees that speed-up grows as $P \times T$ while the number of threads/processor is less than or equal to the size of the pipeline, and beyond that point speed-up grows with the number of processors (because the processor is fully loaded).

### 4.1 Problem 1

### 4.1.1 Problem Description and Algorithm

The problem is to estimate the value of the integral of $f(x)$ in the interval $[\mathrm{a}, \mathrm{b}]$. The formula is

$$
T_{N}=h *\left(\frac{f(a)+f(b)}{2}+\sum_{i=1}^{N-1} f(a+i * h)\right)
$$

where $N$ is the number of intervals in for the estimate and, $h=(b-a) / N$. Increasing $N$ improves the accuracy of the estimate. ${ }^{1}$

### 4.1.2 Inherent Parallelism

The serial solution grows as $\mathcal{O}(N)$. The summation of all the terms can be done in parallel in $\mathcal{O}(\lg N)$ time using $\mathcal{O}(N / 2)$ processors.

### 4.1.3 Characteristics of Translation

First a sequence (in this case the $x_{i}$ values) is built, one then applies the function, and reduces the results (in this case by summation). The parallel algorithm contains extra multiplications to avoid some serial bottlenecks.

### 4.1.4 Performance

Although the single processor, single thread/processor execution time is $\mathcal{O}(N)$ as predicted, the parallel execution time grows nearly as fast, with speed-up of less than $\mathcal{O}(\lg N)$. Detailed analysis shows that the distl and appndr functions, and the aa PFO are a major bottleneck. Over one third of the execution time was spent distributing <h,initial_value> over the iota o size sequence. Since the current implementation does not make the resultant sequence available until the entire distribution is done, the computation of the segments is delayed until distl has completed. The aa and $\backslash$ PFOs are similarly handicapped. In addition, the sequences are

[^0]operated on via a linear scan instead of a data-parallel or tree structured manner that would yield constant time or logarithmic time performance.

These conjectures are tested by using the "OneTick" debugging option. This special feature of TFP allows certain suspect functions to be timed as if they took only one tick to execute. This was added because these functions take $\mathcal{O}(N)$ time due to the implementation of sequences as linked lists. Had sequences been implemented as trees, these operations could be performed in $\mathcal{O}(\lg N)$ time.

When this option is applied to this problem we see execution time drop dramatically, as much as twenty to one for $N=256$.

### 4.2 Problem 2

### 4.2.1 Problem Description and Algorithm

This problem computes $e^{*}$ by:

$$
e^{*}=\sum_{i=1}^{n} \prod_{j=1}^{m}\left(1+e^{(-|i-j|)}\right)
$$

Two nested loops with reduction operators solve this problem easily. The algorithm follows the formula above.

### 4.2.2 Inherent Parallelism

The serial complexity of this is simply $\mathcal{O}(N \times M)$. By using $N \times M$ processors, each of the terms can be computed in constant time. Each of the $N$ sets of $M$ terms can then be multiplied in $\mathcal{O}(\lg M)$ time using $\mathcal{O}(N)$ processors. The $N$ results can then be added in $\mathcal{O}(\lg N)$ time using $\mathcal{O}(N)$ processors. As tested, $M$ and $N$ are given the same value, so the parallel time complexity simplifies to $\mathcal{O}(\lg N)$ time using $\mathcal{O}\left(N^{2}\right)$ processors.

### 4.2.3 Characteristics of Translation

Both the $\Sigma$ and $\Pi$ operations are easy to express in FP. The only shortcoming in the language is that one has to know that one has to pass the values of $n$ and $m$ to the inner function. As a consequence, one builds a sequence of pairs to which the function is applied. This requires some care, but it is not especially tricky.

### 4.2.4 Performance

Empirical results showing the time taken by a single processor matches nicely with theory.

However, when maximal parallelism is allowed, the time grows faster than $\mathcal{O}\left(\lg ^{2} N\right)$, but slower than $\mathcal{O}(N)$, while using fewer than $N^{2}$ processors. This performance was so disappointing that further analysis was done to find the reason. When the tests were re-run with distl and distr running in "OneTick", the times grew slower longer. This suggests that the data structure for sequences has again contributed to the low performance. (And it's worth noting that the iota function appears several times in this program, and it is also linear in its implementation.)

### 4.3 Problem 3

### 4.3.1 Problem Description and Algorithm

Compute the value of

$$
S=\sum_{i=1}^{n} \prod_{j=1}^{m} a_{i j}
$$

This is a straightforward problem that multiplies elements of each row and adds each of the products to a final sum. The algorithm strips off each row for product formation in an inner loop and then sums them in an outer loop.

### 4.3.2 Inherent Parallelism

The serial complexity is $\mathcal{O}(N \cdot M)$, but with $N \cdot M / 2$ processors one can compute all the terms to the summation in $\mathcal{O}(\lg M)$ time, and with $N / 2$ processors one can sum in $\mathcal{O}(\lg N)$ time.

### 4.3.3 Characteristics of Translation

This is close to Problem 2 in expression, but the programming is trivial. This is because the issue of passing parameters to an inner function is missing. In addition, because the input matrix is completely specified, one needn't generate a sequence of values for the internal function.

### 4.3.4 Performance

Empirical results showing the time taken by a single processor are slightly greater than theory predicted, but less than $\mathcal{O}\left(N^{2} \lg N\right)$.

When maximal parallelism is allowed, the time grows faster $\mathcal{O}\left(\lg ^{2} N\right)$. In this case, the PFO $\ /$ is suspect. When the function being inserted is simple, as is the case here, the behavior of the $\backslash /$ PFO becomes visible. When more complex functions are being inserted, or when the evaluation of the terms is complex, this delay is masked.

### 4.4 Problem 4

### 4.4.1 Problem Description and Algorithm

Compute the value of

$$
R=\sum_{\substack{i=1 \\ x_{i} \neq 0}}^{n} \frac{1}{x_{i}}
$$

This problem sums operands whose denominators are nonzero.

### 4.4.2 Inherent Parallelism

The serial complexity is $\mathcal{O}(N)$, but when using $N$ processors, the $N$ terms can be computed in parallel, and then $N / 2$ processors can be used to sum the terms in $\mathcal{O}(\lg N)$ time.

### 4.4.3 Characteristics of Translation

An input sequence of the $x_{i}$ is generated. The function is then applied to all terms in parallel and the sum taken.

### 4.4.4 Performance

While the single processor/single thread execution times grow only slightly faster than $N$, the maximally parallel performance is very poor. For reasons given with previous problems, the rather serial implementation of the $\backslash /$ PFO comes to dominate the program. With the simple function being applied, parallelism grows at an abysmal $\mathcal{O}(\lg N)$ rate.

### 4.5 Problem 5

### 4.5.1 Problem Description and Algorithm

Given a table of the $i^{t h}$ student's scores on the $u^{\text {th }}$ test, perform the following computations:
(a) list the top score for each student
(b) give the number of scores above the average
(c) increase all the above average scores by $10 \%$
(d) give the lowest score that is above average
(e) note whether any student has all scores above average

The algorithm for this problem takes a two-dimensional array of grades and computes a new matrix of grades whose above average scores have been increased by $10 \%$ (c). I assumed that the intent of the computation of the lowest score above the average (d) was to be done prior to increasing the scores by $10 \%$.

### 4.5.2 Inherent Parallelism

There are a number of reduction operations on arrays, compute average, find top, test against average, etc., suggesting the problem's parallel complexity is $\mathcal{O}(\lg N)$. While the operations on the array elements are highly parallel, there are a number of sequential restrictions throughout the computations. For example, the average score for all tests and students must be computed prior to computing the number of scores above the average (b) or increasing all scores above the average by $10 \%$ (c). Thus this problem is a good example of several highly parallel operations separated by barrier points at which the execution must be sequential. Fortunately these barriers are fixed in number, so the complexity measure is unchanged. ${ }^{2}$

### 4.5.3 Characteristics of Translation

The problem statement was ambiguous in many ways, some of which could affect the program structure, e.g. is the top score from the original dataset, or after step (c) has been applied. Once these were resolved, the programming was straightforward.

I often found myself drawing pictures of the current sequence just to keep track of the where the data were. This small handicap in the language is largely compensated by the fact that once it's right, changing input data sizes doesn't affect the solution.

### 4.5.4 Performance

The single processor/single thread execution time grows as $N^{2}-$ this is not surprising as the test dataset had the number of scores grow at the same rate as the number of students. The maximally parallel execution times grow faster than expected - far beyond $\mathcal{O}(\lg N)$ or even $\mathcal{O}\left(\lg ^{2} N\right)$. Again, the processing of sequences in PFOs and functions, especially trans, are suspect.

### 4.6 Problem 6

### 4.6.1 Problem Description and Algorithm

The description of the algorithm was unavailable beyond its implementation in FORTRAN.

[^1]
### 4.6.2 Inherent Parallelism

While it is possible to solve a tridiagonal system, the "vector oriented algorithm of Jordan" contains trickery that involves violation of array bounds and some assumptions about storage that are wholely inappropriate in a language such as FP.

While it is suspected that the available parallelism falls somewhere between elimination methods and iterative methods, no formal analysis has been done.

### 4.6.3 Characteristics of Translation

This problem has not been implemented in FP.

### 4.7 Problem 7

### 4.7.1 Problem Description and Algorithm

The problem is to compute polynomial interpolent values of $f(x)$ using Lagrange interpolation formulae, given by:

$$
p(x)=\sum_{i=1}^{N} f\left(x_{i}\right) l_{i}(x) \text { with } l_{i}(x)=\prod_{\substack{j=1 \\ i \neq j}}^{N}\left(x-x_{j}\right) / \prod_{\substack{j=1 \\ i \neq j}}^{N}\left(x_{i}-x_{j}\right)
$$

### 4.7.2 Inherent Parallelism

This has $\mathcal{O}\left(N^{2}\right)$ serial complexity, but with $\mathcal{O}\left(N^{2}\right)$ processors the $l_{i}(x)$ terms can be computed in $\mathcal{O}(\lg N)$ time and then summed in $\mathcal{O}(\lg N)$ time.

### 4.7.3 Characteristics of Translation

The recurring idiom of building a vector or a matrix of indices and then computing the function at those points, is used in this program.

An initial program version was derived directly from the formula. It did not, however, retain the value of the $f\left(x_{i}\right) /\left(x_{i}-x_{j}\right)$ term. The code in the final program does, but it doesn't yet exploit this in computing the results for the multiple input values.

It's interesting to note that the two program versions return slightly different values because of the sum-then-div in one and the div-then-sum in the other.

### 4.7.4 Performance

Serial performance agrees with theory. The execution times for parallel execution grew as $\mathcal{O}(N)$ (as parallelism grew only sightly better than $N$ ). Using the OneTick option for a number of the functions and PFOs kept the parallel execution times in the $\mathcal{O}(\lg N)$ realm longer, but the system eventually succumbs to the access time for linear sequences.

### 4.8 Problem 8

### 4.8.1 Problem Description and Algorithm

These formulae define the divided difference table for a set of data $x_{i}, y_{i}=\mathrm{f}\left(x_{i}\right)$ :

$$
\begin{gathered}
f\left[x_{i}\right]=y_{i} \\
f\left[x_{i}, x_{i+1}, \ldots, x_{i+k}\right]=\frac{f\left[x_{i+1}, \ldots, x_{i+k}\right]-f\left[x_{i}, \ldots, x_{i+k-1}\right]}{x_{i+k}-x_{i+k-1}}
\end{gathered}
$$

The problem is to compute the first $M$ columns of the divided difference table

$$
D_{i k}=f\left[x_{i}, x_{i+1}, \ldots, x_{i+k-1}\right]
$$

### 4.8.2 Inherent Parallelism

Each new column of the divided difference table is derived from the previous column of the difference table. It can be computed in constant time using $N$ processors. Even if each element of that column were to be computed directly from the first column (the $y_{i}$ values), the computation performance would be limited by the number of stages needed in the computation. No speed-up would be found in this approach, so we compute each column after the previous one is done.

The maximum parallelism is found in computing the first divided difference column. Remaining columns have less available parallelism.

### 4.8.3 Characteristics of Translation

Unlike FORTRAN or SISAL, it's rather difficult in FP to index into a sequence representing a column or row. The FP solution is to extract the previous column twice, shift one of the two columns, transpose, and subtract. The rest of the code is "glue" to hold the program together.

### 4.8.4 Performance

Empirical results show the single processor /single thread execution time grows much faster than theory suggests, $\mathcal{O}\left(N^{2}\right)$ rather than $\mathcal{O}(N)$.

The parallel performance is similarly sluggish. Average parallelism and execution times grow by $\mathcal{O}(N)$. The continued manipulation of the intermediate results by the append function costs dearly. Although this program produces the correct result, it is a good candidate for optimization such as computing all the columns simultaneously. Such a version would avoid almost all the copying that is being performed by the append function.

### 4.9 Problem 9

### 4.9.1 Problem Description and Algorithm

This problem is to smooth a matrix of real values. The computation is useful in image processing, solving differential equations, and geometric modeling and therefore is typical of much scientific computing. The matrix is smoothed by taking the average of each cell in the matrix with all its neighbors. That is,

$$
u_{i j}=\left(\sum_{\text {Neighbors }} u_{i j}\right) /(\text { Number of neighbors })
$$

### 4.9.2 Inherent Parallelism

For an $N \times N$ matrix, serial computation is $\mathcal{O}\left(N^{2}\right)$ and parallel computation takes constant time with $N^{2}$ processors.

### 4.9.3 Characteristics of Translation

As mentioned in Section 2, Language Idioms, this matrix is replicated nine times and each copy is shifted appropriately so that an average across the Z axis yields the appropriate result.

The boundaries caused a few problems in that the problem statement only implied what was to be done. The programming would have been a little easier if the trans function allowed irregular shapes to be transposed. As it was, significant effort is expended to "fill in" the irregularities.

### 4.9.4 Performance

Because of the boundary problems mentioned above, functions such as tl and length were needed to adjust sequences. These functions prevented the program from achieving its full potential. In spite of this, parallelism still grew much faster than $\mathcal{O}(N \lg N)$. N.B. This is a deceptive improvement because of the tremendous overhead in the shifting. The modified trans function mentioned above would be a much cleaner implementation.

### 4.10 Problem 10

### 4.10.1 Problem Description and Algorithm

The problem is LU factorization of an $N \times N$ matrix $A=a_{i j}$ using Gaussian elimination with partial pivoting.

### 4.10.2 Inherent Parallelism

Although finding the pivot element (maximum element in a column) can be done in parallel, and adjusting the remaining rows can be done in parallel, This problem has a fundamentally serial nature. One cannot find a pivot row $K$ until the processing of row $K-1$ has been completed.

In spite of these recurring barriers, there still would be sufficient parallelism, but for the costs of copying matrices as the rows are shifted. A shuffle function that pays careful attention to reference counts, so it could "copy in place", would prove very useful.

### 4.10.3 Characteristics of Translation

This problem has not been implemented in FP.

### 4.11 Problem 11

### 4.11.1 Problem Description and Algorithm

The problem is to read a set of $N$ real numbers $n_{i}$, trim the numbers to fall within the range [ 0,1000 ], and apply a $\log$ arithmic transformation $\boldsymbol{d}_{i}=\log \left(1+n_{i}\right)$, and then compute the first four Fourier moments according to the formula:

$$
\text { fourier }- \text { moment }(k)=\left(\sum_{i=1}^{N} d_{i} \cos (\pi i /(k+1))\right) / N
$$

where $k$ is $1,2,3$ or 4 .

### 4.11.2 Inherent Parallelism

This problem contains significant inherent parallelism. With $\mathcal{O}(N)$ processors, each term of the sum in each Fourier moment can be computed in parallel in constant time. The summation then takes $\mathcal{O}(\lg N)$ time.

### 4.11.3 Characteristics of Translation

The problem was easily divided into three phases: one to limit ranges, the next to distribute vector length and index across vector values, and finally one to compute moments. The only problem is in the large degree of indentation that shows up in the program listing.

### 4.11.4 Performance

Although it was possible to construct the test data with the index and array size bound to each value, it wouldn't have been a proper use of the expressive power of the language. Instead the vector is first built and is then processed.

Serial execution times grew slightly faster than the $\mathcal{O}(N)$ predicted by theory. Parallel execution times grew slightly slower than $\mathcal{O}(N)$. The average parallelism grew a bit faster than $\mathcal{O}(\lg N)$. A brief check showed that the shuffle function (shown in the program listing) uses up over half the time (due to the linear nature of trans).

### 4.12 Problem 12

### 4.12.1 Problem Description and Algorithm

This problem is similar to Problem 9 in that a matrix is built from a previously existing matrix. But here the new matrix results from a smaller matrix, two vectors, and a scalar. Rice states this problem as:

Given the $m \times m$ matrix $A$, the $1 \times m$ vector $R$, the $m \times 1$ vector $C$, and a number $a$, build the array

$$
A B I G=\left[\begin{array}{c}
A C \\
R a
\end{array}\right]
$$

### 4.12.2 Inherent Parallelism

In serial execution, $\mathcal{O}\left(N^{2}\right)$ time is needed to copy the $N^{2}$ elements. In a data parallel system, this could be done in constant time. This implementation's parallelism is limited only by the ability to build a sequence and then populate its elements. The apndr and append functions are linear in this version, but could be $\mathcal{O}(\lg N)$ if the sequences were tree structured.

### 4.12.3 Characteristics of Translation

The code so easily captures the solution that the program is shorter than the description. It seems almost too easy, but it works!

### 4.12.4 Performance

Serial execution runs in $\mathcal{O}\left(N^{2}\right)$ time as predicted. Parallel execution times show only a modest 10 to 1 improvement over serial execution. The serialization in append, trans, and apndr is the culprit. The OneTick option only pulls the times down to $\mathcal{O}(N)$ because the trans function really isn't speeded up that much due to its internal use of selection functions.

### 4.13 Problem 13

### 4.13.1 Problem Description and Algorithm

For vectors $a, b, c$, and $d$, recompute $a$ with the procedure:

$$
\begin{aligned}
& \quad a_{i}=a_{i}^{\sin \left(b_{i}\right)} \\
& \\
& \quad \text { If }\left(a_{i}<\cos \left(b_{i}\right)\right) \text { then } a_{i}=a_{i}+c_{i} \\
& \\
& \quad \text { else } a_{i}=a_{i}-d_{i} \\
& \\
& \text { and compute } \\
& e
\end{aligned}
$$

The algorithm reads the $a_{i}$ array, creating a new value for each instantiation of $a_{i}$ and finally returns a new vector and a sum. N.B. See the comments about documented versus actual formulae in the section "Characteristics of Translation."

### 4.13.2 Inherent Parallelism

Each of the new $a_{i}$ elements can be computed in constant time using $\mathcal{O}(N)$ processors. The summation then takes $\mathcal{O}(\lg N)$ time.

### 4.13.3 Characteristics of Translation

As with many of these problems, the dataset is "turned sideways" and the operations are then applied to all of the tuples in parallel.

The original Rice paper said $a i=a i * \sin (b i)$, but the Fortran code says $a i=a i * * \sin (b i)$. Later the papers test $a i<\cos (c i)$, but the code tests $\sin (a i)<\cos (c i)$. This program matches the operations of the actual code.

A "DOMAIN ERROR" forced the insertion of abs $\circ$ in the computation of ai**sin(bi) to ensure that the power function works properly.

### 4.13.4 Performance

Serial execution times grew a little faster than $\mathcal{O}(N)$ Unfortunately parallel execution times grew nearly as fast as $\mathcal{O}(N)$. Average parallelism grew as $\mathcal{O}(\lg N)$. As with Problem 11, a brief check of trans showed it to cause much of the delay.

I tried pulling the [id,id] into the conditional as $[+,+]$ and $[-,-]$ to little effect. This suggests that the predicate is known soon enough to let the [id,id] pick up a conditional. Or possibly the single tick improvement was lost in the noise.

### 4.14 Problem 14

### 4.14.1 Problem Description and Algorithm

This problem carries out a test of three methods to integrate three separate functions with 50 different levels of accuracies. The original problem used four methods; trapezoidal integration, Simpson's rule, 3-point Gaussian integration, and the DCADRE specialized algorithm. I decided that the first two were enough for testing parallelism in this type of environment.

### 4.14.2 Inherent Parallelism

In this problem, the problem set size is the number of intervals over which the functions are to be integrated.

Full parallelism is found at the outer level because each test is independent. Within each test, each term of the numerical integration can be computed in constant time using $N$ parallel tasks. The terms can then be added in $\mathcal{O}(\lg N)$ time.

### 4.14.3 Characteristics of Translation

This shows one major limitation of FP as a language. The decision to prohibit user defined PFOs prevents one from defining an integration PFO that is applied to a function and object. Instead, one must re-write the integration function for each of the test functions.

Another approach would be to "pass the function" via the name binding mechanism, invoking the program once for each of the user functions.

### 4.14.4 Performance

Serial execution times grew as $\mathcal{O}(N)$. Parallel execution times grew nearly as fast, but the average parallelism grew as $\mathcal{O}(\lg N)$.

### 4.15 Problem 15

### 4.15.1 Problem Description and Algorithm

The problem is to compare two types of interpolation points (equispaced and Chebyshev spaced) for Hermite interpolation using piece-wise polynomials. The interpolant's value $v$ at $y$ is

$$
v(y)=\sum_{j=1}^{N} f\left(x_{j}\right) h_{1 j}(y)+f^{\prime}\left(x_{j}\right) h_{2 j}(y)
$$

where $h_{1 j}(x)$ and $h_{2 j}(x)$ are suitable basis functions that depend on the $N$ interpolation points $x_{j}$.

### 4.15.2 Inherent Parallelism

At the outermost levels there is modest parallelism across the types of interpolation points. Within that, there is the evaluation to be performed at each of the interpolation points: $\mathcal{O}(k)$ time using $\mathcal{O}(N)$ processors. These points are then summed in $\mathcal{O}(\lg N)$ time using $\mathcal{O}(N)$ processors.

### 4.15.3 Characteristics of Translation

This problem has not been implemented in FP, due only to lack of time.

### 4.16 Problem 16

### 4.16.1 Problem Description and Algorithm

This problem is to solve the matrix equation $A x=B$ where $A$ is an $N \times N$ Hilbert matrix and $B$ is an $N \times 4$ matrix. The matrix order $N$ takes on the values $4,9,16,25,36, \ldots$ and the $B$ column-vectors are, respectively, the first column of the identity matrix, all 1 's, a random perturbation of $1.0 \pm 0.01$ in all elements, and alternating $+1,-1$.

### 4.16.2 Inherent Parallelism

The problem statement leaves open the method to be used to solve the problem. I chose an iterative method to compute the matrix inverse, $C$, which can then be multiplied by $B$ to yield the answer. This method has tremendous parallelism and serial time complexity comparable to direct methods for most matrices.

The serialization is limited only to the test at each iteration, and it is possible to proceed in parallel with the next iteration using the while PFO.

### 4.16.3 Characteristics of Translation

The problem can be restated again as "Compute $C$, an $N \times N$ inverse of an $N \times N$ matrix, such that the product $(C \times A)$ is a $N \times N$ matrix "close" to the Identity matrix. Then multiply this inverse times the $B$ column-vectors."

Houseman's method [Hou64] is similar in form to Newton's method of finding a root (but operates on matrices).

Each iteration step computes $C_{n+1}$ is $2 C_{n}-C_{n} \times A \times C_{n}$ (derived from $B \times\left(2 \times I-A \times C_{n}\right)$ or from ( $2 I-C_{n} \times A$ ) $\times C_{n}$ ) Matrix multiplication is easily expressed in FP: one just shuffles rows and columns about until an aa PFO can be used to compute output terms in parallel.

An adequate initial inverse, $C_{1}$, is the transpose divided by the product of the row and column maximums.

### 4.16.4 Performance

Although this technique appears to be robust in terms of many near-singular matrices, it converges painfully slowly with the Hilbert matrix. For this reason, tests have been limited to other, less difficult matrixes.

The matrix size is $\lg (N) \times \lg (N)$, where $N$ is given in these tables. The serial execution times grew as $\mathcal{O}\left(N^{3}\right)$ as would be expected for a naive matrix inversion. Parallelism grew as $\mathcal{O}(N)$, so that parallel execution times grew approximately $\mathcal{O}(N)$. A new implementation of trans and tree-structured sequences should offer significant improvement.

### 4.17 Problem 17

### 4.17.1 Problem Description and Algorithm

The last Purdue technical report [RJ90] added a 17th problem - adaptive quadrature. The report did not formally specify what was to be done, rather it referred to textbooks that discussed various implementations of AQ [Ric75],[Ric76].

### 4.17.2 Inherent Parallelism

Given truly independent parallelism - not that of many SIMD systems - AQ offers large, but irregular parallelism.

One does not know a priori the degree of parallelism. The degree of parallelism is instead derived from the function being evaluated. Parallelism grows exponentially and the interval is
divided into finer and finer pieces; it then decays exponentially as the sub-interval integrals are summed.

There are two controlling factors: the function being evaluated and the error term demanded of the solution.

### 4.17.3 Characteristics of Translation

A simple trapezoidal rule is used to evaluate the integral for an interval and for two half intervals. If the difference is small enough, the sum of the half intervals is used, if not, the sum of the results of a recursive evaluation is used.

Programming this was puzzling until a data-flow graph was laid out. It was then possible to recognize the several phases in each level. These phases were described in individual functions that passed some parameters through unchanged while changing or creating new parameters for the function in the next phase. Because of the recursive doubling that can occur, it may not qualify as a systolic algorithm, but it has that feel to it.

### 4.17.4 Performance

Up until this problem, the idea of "problem set size" has been a simple concept. One just counts the elements to be summed, sorted, averaged, etc. Adaptive quadrature specifically avoids an external specification of how many intervals are to be used. As a consequence one has to shift the problem in subtle ways to evoke greater parallelism.

In this test, parallelism was adjusted by controlling the error term. Reasonable results were found by setting the error term to the reciprocal of what we have heretofore called the "problem set size", $N$.

One sees the parallelism initially grows with $N$, but even while the maximum parallelism keeps growing, the average seems to be approaching an asymptote of about 100. I suspect that the exponential growth (due to the recursive doubling) keeps the maximum parallelism high, while the average parallelism is dominated by the function itself.

## 5 Conclusion

Table 1 summarizes the theoretical and actual parallel performance found in the problems.
This implementation of FP has some fundamental limitations in exploiting the full parallelism available in the language. These limitations generally center on the linked list used to represent sequences and the functions and PFOs that operate upon them. In spite of this, many of these programs still show surprising, and gratifying to the author, parallel performance. In five cases

Table 1: Complexity and performance of problems

| Prob | Theoretical |  | Actual |  |
| :---: | :---: | :---: | :---: | :---: |
|  | Serial | Parallel | Serial | Parallel |
| 1 | $\mathcal{O}(N)$ | $\mathcal{O}(\lg N)$ | $\mathcal{O}(N)$ | $\mathcal{O}(N)$ |
| 2 | $\mathcal{O}\left(N^{2}\right)$ | $\mathcal{O}(\lg N)$ | $\mathcal{O}\left(N^{2}\right)$ | $\mathcal{O}\left(\lg ^{2} N\right)<\mathcal{O}(N)$ |
| 3 | $\mathcal{O}\left(N^{2}\right)$ | $\mathcal{O}(\lg N)$ | $\mathcal{O}\left(N^{2} \lg N\right)$ | $\mathcal{O}\left(\lg ^{2} N\right)$ |
| 4 | $\mathcal{O}(N)$ | $\mathcal{O}(\lg N)$ | $\mathcal{O}(N)$ |  |
| 5 | $\mathcal{O}\left(N^{2}\right)$ | $\mathcal{O}(\lg N)$ | $\mathcal{O}\left(N^{2}\right)$ | $\gg \mathcal{O}\left(\lg ^{2} N\right)$ |
| 6 | not calculated |  | not implemented in FP |  |
| 7 | $\mathcal{O}\left(N^{2}\right)$ | $\mathcal{O}(\lg N)$ | $\mathcal{O}\left(N^{2}\right)$ | $\mathcal{O}(N)$ |
| 8 | $\mathcal{O}(N)$ | $\mathcal{O}(1)$ | $\mathcal{O}\left(N^{2}\right)$ | $\mathcal{O}(N)$ |
| 9 | $\mathcal{O}\left(N^{2}\right)$ | $\mathcal{O}(1)$ | $\mathcal{O}\left(N^{2}\right)$ | $\mathcal{O}(N)$ |
| 10 | not calculated |  | not implemented in FP |  |
| 11 | $\mathcal{O}(N)$ | $\mathcal{O}(\lg N)$ | $>\mathcal{O}(N)$ | $<\mathcal{O}(N)$ |
| 12 | $\mathcal{O}\left(N^{2}\right)$ | $\mathcal{O}(1)$ | $\mathcal{O}\left(N^{2}\right)$ | $\mathcal{O}\left(N^{2}\right)$ |
| 13 | $\mathcal{O}(N)$ | $\mathcal{O}(\lg N)$ | $>\mathcal{O}(N)$ | $<\mathcal{O}(N)$ |
| 14 | $\mathcal{O}(N)$ | $\mathcal{O}(\lg N)$ | $\mathcal{O}(N)$ | $<\mathcal{O}(N)$ |
| 15 | not calculated |  | not implemented in FP |  |
| 16 |  |  | $\mathcal{O}\left(N^{3}\right)$ | $\mathcal{O}\left(N^{2}\right)$ |
| 17 | Inappropriate measure | Not known a priori | not reported |  |

(problems 2, 7, 9, 16, and 17) the speedups were greater than 50 for problem set sizes of only 32. In at least one case (problem 7) the speedup grew faster than $\mathcal{O}(N)$ !

It is not surprising to note that while a PFO such as / is the most efficient in a single processor /single thread environment, the $\backslash /$ variation is better designed to identify and exploit greater parallelism. This suggests that an advanced implementation would dynamically choose the appropriate evaluation strategy for a generalized insert PFO based on system load.

|  |  |  |  |  |  |
| 8 |  |  |  |  |  |

In the following, the "OneTick" option was used to give distl and distr a simulated duration of only one tick each. This allows us to examine the effects of more efficient implementations of these functions.

In the following, the "OneTick" option was used to give distl and distr a simulated duration of only one tick each. This allows us to examine the effects of more efficient implementations of these functions.

## . 7 Source Listing of Problem 7

```
# Problem 7
# Compute polynomial interpolant values of f(x) at
# five points using Lagrange interpolation formulas....
#
# The formulation immediately below is derived
# directly from the formula. It doesn't, however,
# retain the value of the "f(xi)/(xi-xj)" term.
# The formulation in the real code does, but it
# doesn't yet exploit this in computing for the
# multiple input values.
#
# It's interesting to note that the two formulations
# return slightly different values because of the
# sum-then-div in one and the div-then-sum in the
# other.

\# Although it was possible to construct the test data with the
\# index and array size bound to each value, it wouldn't have
\# been a proper measure of the expressive power of the language.
\# Instead the vector is first built and is then processed.

## . 14 Source Listing of Problem 14

\# Problem 14
\# Test four integration methods
\# (trapezoidal, Simpson's, Runga-Kutta(?))
\# on three functions
\# (exp, sqrt(abs(x-.2345)), 2.+101.*x*x)
\# at ten levels of accuracy.
\# (10, 25, 50, 75, 100, 150, 200, 300, 500, 1000 parts)
\# This problem is the first that shows the shortcoming
\# of FP vis a vis other functional languages. Since
\# only the "standard" PFOs may operate on functions,
\# one cannot define new PFOs to perform integration of
\# functions over intervals. As a consequence, one must
\# program each function into each integration method.
\# The first function, range to be integrated, and the "correct" answer Def f1
