October 12, 2006

Abstract

The polyhedral model is extensively used for analyses and transformations of regular loop programs, one of the most important being automatic parallelization. The model, however, is limited in expressivity and the need for the generalization to more general class of programs has been widely known. Analyses and transformations in the polyhedral model rely on certain closure properties. Recently, these closure properties were extended to programs where variables may be defined over unions of \( \mathcal{Z} \)-polyhedra, intersections of polyhedra and lattices.

We present the scheduling analysis for the automatic parallelization of programs in the \( \mathcal{Z} \)-polyhedral model, and obtain multidimensional schedules through an ILP formulation that minimizes latency. The resultant schedule can then be used to construct a space-time transformation to obtain an equivalent program in the \( \mathcal{Z} \)-polyhedral model.

1 Introduction

The polyhedral model is a well developed formalism providing sophisticated analysis and transformations of the kernels of many compute- and data-intensive applications. Programs in the polyhedral model essentially comprise of (i) variables representing collections of values defined over polyhedral domains\(^1\), and (ii) affine dependences between computations. Feautrier [5] showed that an important class of conventional imperative loop programs called affine control loops (ACLS) can be transformed to programs in the polyhedral model. Significant parts of the SpecFP and PerfectClub benchmarks are ACLS [1].

Many computations can be expressed in the polyhedral model, e.g., matrix multiplication, LU-decomposition, Cholesky factorization, Kalman filtering, as well as algorithms arising in RNA secondary structure prediction. Nevertheless, the polyhedral model suffers from certain limitations. Loop programs with a non-unit stride fall outside the scope of the model. This is an important class of programs [22, 15, 27, 8] arising in situations such as the red-black SOR computation for solving partial differential equations. As a consequence, non-unimodular

\(^{1}\)These may be viewed as generalized multi-dimensional arrays, the bounds of which are given by arbitrary affine inequalities.

\(^{2}\)This research was supported in part by the National Science Foundation, under the grant EI-030614: HiPHiPECS: High Level Programming of High Performance Embedded Computing Systems.
transformations are also disallowed in the polyhedral model. Non-unimodular transformations are required for the derivation of parallel architectures with periodic processor activity, such as multi-rate arrays [14] and bidirectional systolic arrays.

It had long been conjectured that these limitations can be resolved through the extension of variable domains to unions of $\mathbb{Z}$-polyhedra which are the intersection of polyhedra and affine lattices. However, the required closure properties for these $\mathbb{Z}$-polyhedral domains were only recently proved [9], as a result of a novel representation for $\mathbb{Z}$-polyhedra and the associated family of dependences.

The $\mathbb{Z}$-polyhedral model enables more sophisticated analyses and transformations by providing greater information in the specifications viz., pertaining to lattices. More importantly, the $\mathbb{Z}$-polyhedral model allows specifications with a more general dependence pattern than the specifications in the polyhedral model.

**Example 1** Consider the following loop program

for $i = 1$ to $N$
  $A[i] = (i \& 2 == 0 ? A[i/2] : 0)$;

This program exhibits a dependence pattern that is richer than the affine dependences of the polyhedral model. In other words, it is impossible to write an equivalent program in the polyhedral model, i.e., without the use of the mod operator, that can perform the required computation. One may consider replacing the variable $A$ by two variables $X$ and $Y$ corresponding to the even and odd points of $A$ such that $A[2i] = X[i]$ and $A[2i - 1] = Y[i]$. However, the definition of $X$ now requires the mod operator, because $X[2i] = X[i]$ and $X[2i - 1] = Y[i]$.

Automatic parallelization is one of the most important and widely studied analysis in the polyhedral model [11, 12, 6, 7, 2, 21, 20, 16, 3, 23, 24, 17, 19]. This paper presents an algorithm for scheduling the more general programs of the $\mathbb{Z}$-polyhedral model. Our key contributions are (i) deriving precedence (causality) constraints for programs written in the $\mathbb{Z}$-polyhedral model, (ii) formulation of an integer linear program to obtain a schedule which is based on Farkas method and minimizes latency, and (iii) the generalization of the scheduling problem to multi-dimensional schedules. A important feature of our formulation is that it seeks schedules that can be used to construct a program transformation to obtain an equivalent specification in the $\mathbb{Z}$-polyhedral model\(^2\).

The remainder of this paper is organized as follows. In the following section, we give a example to motivate the scheduling problem for programs written in the $\mathbb{Z}$-polyhedral model. The mathematical background on lattices, polyhedra, $\mathbb{Z}$-polyhedra and affine functions is described in section 3. In section 4, we describe an equational language for high level specifications in the $\mathbb{Z}$-polyhedral model and present reduced dependence graphs as the required abstraction for our analysis. In section 5, we derive precedence constraints and then formulate an ILP to obtain valid (multidimensional) schedules. Finally, we discuss future and related work and present our conclusions.

\(^2\)This has been a major drawback of previous methods using rational schedules.
2 Motivating Example

Consider the following loop program:

Example 2

\[
\begin{align*}
&\text{for } i = 0 \text{ to } N \\
&\quad \text{for } j = 0 \text{ to } N \\
&\quad \quad X[i, j] = (i/2 == 0 \ ? X[i, j-1] : Y[i-1, j]); \\
&\quad \text{for } j = N \text{ down to } 0 \\
&\quad \quad Y[i, j] = (i/2 == 0 \ ? X[i, j] : Y[i, j+1]);
\end{align*}
\]

In order to parallelize this affine loop program extracting data dependence relations is a first and critical step. Such dependence relations should be respected in any parallelized program. Otherwise, the semantics of a program will not be preserved.

In order to know dependence relations, we now apply exact dataflow analysis [5], a well-known technique for extracting dependence relations. The obtained data dependence information are shown in Figure 1. A node in data dependence graph represents an iteration point of a statement, and the arrow between nodes specifies data-flow between two operations.

Now, we want to parallelize this computation. Because of the vertical dependence on \(X\), the execution order of \(X\) will be increasing order of \(j\) index. Similarly, the execution order of \(Y\) will be decreasing order of \(j\). Together with dependences between \(X\) to \(Y\), this computation must be done sequentially exactly like the original loops, that is, for each \(i\), first computing \(X\) in the increasing order of \(j\) and then computing \(Y\) in the decreasing order of \(j\), repeating this for \(i+1\) until the whole computation finishes.

One may find one dimensional parallelism in the program by distinguishing true dependence from false dependence as shown in Figure 1. In the figure the true dependence are
denoted with black arrows. The precise execution order can be given and realized by the following schedules and parallelized loop program, respectively:

\[
\text{for } j = 0 \text{ to } N \\
\text{forall } i \text{ to } (N/2) \\
\lambda_X(i, j) = \begin{cases} 
  \text{i even :} & j \\
  \text{i odd :} & j + 2 
\end{cases} \\
\lambda_Y(i, j) = \begin{cases} 
  \text{i even :} & j + 1 \\
  \text{i odd :} & N - j 
\end{cases}
\]

Note that the loop program is correct only when \( N \) is odd. For the sake of simplicity, we assume that \( N \) is odd. We also assume that the statements are executed sequentially, i.e., there is synchronization between statements.

The key idea of this detection is based on precise information on dependence relations by separating a rectangle, called polyhedron, into two disjoint rectangle with holes, called \( \mathcal{Z} \)-polyhedra. Note that the actual representation of data dependence graph in Figure 1 is the RDG. Since \( N \) is not known at compile time, the data dependence graph is not possible to construct. The precise data dependence relations are shown in Figure 2.

In this paper we address the problem of scheduling together with constructing RDG in \( \mathcal{Z} \)-polyhedral model. One may argue that the example has an equivalent loop program where parallelism can be detected even in Polyhedral model. As we argue in the introduction, every program in \( \mathcal{Z} \)-polyhedral model does not have an equivalent program in Polyhedral model. Also, it is not always obvious to write programs so that parallelism can be detected in Polyhedral model.
3 Mathematical Background

Here, we will provide the required mathematical background on linear algebra over integers.

3.1 Matrices

As a convention, we will denote matrices with the upper-case letters and vectors with the lower-case. Unless specifically mentioned, all matrices and vectors have integer elements. We will denote the identity matrix by $I$. Syntactically, the different elements of a vector $v$ will be written as a list.

We will use the following concepts and properties of matrices

- The kernel of a matrix $T$, written as $\ker(T)$ is the set of all vectors $z$ such that $Tz = 0$.
- A matrix is unimodular if it is square and its determinant is either 1 or $-1$.
- Two matrices $L$ and $L'$ are said to be column equivalent or right equivalent if there exists a unimodular matrix $U$ such that $L = L'U$.
- A unique representative element in each set of matrices that are column equivalent is the one in Hermite normal form [10].

**Definition 1** An $n \times m$ matrix $H$ with rank $d$ is in Hermite Normal Form (HNF), if

1. $\forall 1 \leq j \leq d, \exists i_1, \ldots, i_d$ with $1 \leq i_1 < \ldots < i_d \leq n$: $H_{i_j, j} > 0$.
2. $\forall 1 \leq j \leq d, 1 \leq i < i_j$: $H_{i, j} = 0$.
3. $\forall d + 1 \leq j \leq m, 1 \leq i \leq n$: $H_{i, j} = 0$
4. $\forall 1 \leq l < j \leq d$: $0 \leq H_{i, l} < H_{i, j}$.

For every matrix $A$, there exists a unique matrix $H$ that is in HNF and column equivalent to $A$ i.e., there exists a unimodular matrix $U$ such that $A = HU$. Note that the provided definition of the Hermite normal form does not require the matrix $A$ to have full row rank.

3.2 Affine Lattices

The lattice generated by a matrix $L$ is the set of all integer linear combinations of the columns of $L$. If the columns of a matrix are linearly independent, they constitute a basis of the generated lattice. The lattices generated by two matrices are equal iff the submatrices corresponding to the non-zero columns in their Hermite normal forms are equal. As a special case, the lattices generated by two $n \times m$ matrices are equal iff the matrices are column equivalent.

We use a generalization of the lattices generated by a matrix, additionally allowing offsets by constant vectors. These are called affine lattices. An affine lattice is a subset of $\mathbb{Z}^n$ and can be represented as $\{Lz + l | z \in \mathbb{Z}^m\}$ where $L$ and $l$ are an $n \times m$ matrix and $n$-vector respectively. We call $z$ the coordinates of the affine lattice.

The affine lattices $\{Lz + l | z \in \mathbb{Z}^m\}$ and $\{L'z' + l' | z' \in \mathbb{Z}^m\}$ are equal iff the lattices generated by $L$ and $L'$ are equal and $l' = Lz_0 + l$ for some constant vector $z_0 \in \mathbb{Z}^m$. 

5
3.3 Integer Polyhedra

An integer polyhedron, \( \mathcal{P} \) is a subset of \( \mathbb{Z}^n \) that can be defined by a finite number of affine inequalities (also called affine constraints or just constraints when there is no ambiguity) with integer coefficients. We follow the convention that the affine constraint \( c_i \) is given as 
\[
(a^T_i z + \alpha_i \geq 0)
\]
where \( z, a_i \in \mathbb{Z}^n, \alpha_i \in \mathbb{Z} \). The integer polyhedron, \( \mathcal{P} \), satisfying the set of constraints \( \mathcal{C} = \{c_1, \ldots, c_b\} \) is often written as 
\[
\{z \in \mathbb{Z}^n | Qz + q \geq 0\}
\]
where \( Q = (a_1 \ldots a_b)^T \) is an \( b \times n \) matrix and \( q = (\alpha_1 \ldots \alpha_b)^T \) is an \( b \)-vector ex. \( \{i, j|0 \leq i, 0 \leq j\} \) is the polyhedron corresponding to the first orthant.

We shall use the following properties and notation.

- The constraint \( c \equiv (a^T z + \alpha \geq 0) \) of \( \mathcal{P} \) is said to be saturated iff \( (a^T z + \alpha = 0) \cap \mathcal{P} = \mathcal{P} \).
- The lineality space of \( \mathcal{P} \) is defined as the linear part of the largest affine subspace contained in \( \mathcal{P} \). It is given by \( \ker(Q) \).
- The context of \( \mathcal{P} \) is defined as the linear part of the smallest affine subspace that contains \( \mathcal{P} \). If the saturated constraints in \( \mathcal{C} \), are the rows of \( \{Q_0 z + q_0 \geq 0\} \), then it is \( \ker(Q_0) \).

3.3.1 Parameterized Integer Polyhedra

A parameterized integer polyhedron is an integer polyhedron where some indices are interpreted as size parameters. We may also interpret a parameterized integer polyhedron as the infinite set of integer polyhedra obtained by exhaustively assigning valid constant values to all size parameters.

3.4 \( \mathcal{Z} \)-Polyhedra

A \( \mathcal{Z} \)-polyhedron is the intersection of an integer polyhedron and an affine lattice. It is also an integer polyhedron when the affine lattice is the canonical lattice, \( \mathbb{Z}^n \). The required closure properties on unions of \( \mathcal{Z} \)-polyhedra were based on the following representation for \( \mathcal{Z} \)-polyhedra.

\[
\{ Lz + l | Qz + q \geq 0, z \in \mathbb{Z}^m \}
\]

where \( L \) has full column rank and the polyhedron \( \mathcal{P}^c = \{z | Qz + q \geq 0, z \in \mathbb{Z}^m \} \) has a context that is the universe, \( \mathbb{Z}^m \). \( \mathcal{P}^c \) is called the coordinate polyhedron of the \( \mathcal{Z} \)-polyhedron. The \( \mathcal{Z} \)-polyhedron for which \( L \) has no columns has a coordinate polyhedron in \( \mathbb{Z}^0 \). The empty \( \mathcal{Z} \)-polyhedron is denoted by \( \{\} \). The interpretation is that the \( \mathcal{Z} \)-polyhedral representation is said to be based on the affine lattice given by \( \{Lz + l | z \in \mathbb{Z}^m\} \). Iteration points of the \( \mathcal{Z} \)-polyhedral domain are points of the affine lattice corresponding to valid coordinates. The set of valid coordinates is given by the coordinate polyhedron.
### 3.4.1 Parameterized Z-Polyhedra

A parameterized $Z$-polyhedron is a $Z$-polyhedron where some rows of its corresponding affine lattice are interpreted as size parameters. We may also interpret a parameterized $Z$-polyhedron as an infinite set of $Z$-polyhedra. The elements of a parameterized $Z$-polyhedron are called its instances.

For the sake of explanation, and without loss of generality, we may impose that the rows that denote size parameters are before all non-parameter rows. The equivalent $Z$-polyhedron based on the Hermite normal form of such a lattice has an important property that will used in our analysis; all points of the coordinate polyhedron with identical values of the first few indices belong to the same instance of the parameterized $Z$-polyhedron.

**Example 3** Consider the $Z$-polyhedron given by the intersection of the polyhedron \{p, i|0 \leq i \leq p\} and the lattice \{j + k, j - k\}$. It may be written as

\[ \{j + k, j - k|0 \leq j - k \leq j + k\} = \{j + k, j - k|0 \leq k \leq j\} \]

Now, suppose the first index, $p$, in the polyhedron is the size parameter. As a result, the first row in the lattice \{j + k, j - k\} corresponding to the $Z$-polyhedron is the size parameter. The Hermite normal form of this lattice is \{j', j' + 2k\}. The equivalent $Z$-polyhedron is

\[ \{j', j' + 2k'|k' \leq 0 \leq j' + 2k'\} \]

The iterations of this $Z$-polyhedron belong to the same program instance if they have the same coordinate index $j'$. Note that valid values of the parameter row trivially have a one-to-one correspondence with value of $j'$; identity being the required bijection. In the general case, however, this is not the case. Nevertheless, the required property remains invariant. For example, consider the following $Z$-polyhedron with the first two rows considered as size parameters.

\[ \{m, m + 2n, i + m, j + n|0 \leq i \leq m; 0 \leq j \leq n\} \]

Here, valid values of the parameter rows have a one-to-one correspondence with the values of $m$ and $n$ but it is impossible to obtain identity as the required bijection.

### 3.5 Affine Functions and Affine Lattice Functions

An (standard) affine function is of the form $(z \to Tz + t)$ where $T$ is an $n \times m$ matrix and $t$ is an $n$ vector. **Affine lattice functions** are of the form $(Kz + k \to Rz + r)$, where $K$ has full column rank. Such functions provide a mapping from the iteration $Kz + k$ to the iteration $Rz + r$. We have imposed that $K$ have full column rank to guarantee that $(Kz + k \to Rz + r)$ be a function and not a relation, mapping any point in its domain to a unique point in its range. All standard affine functions are also affine lattice functions. For any function $f$, $f^{-1}$ will denote its relational inverse.

---

3Note, for both the polyhedron and the affine lattice, the specification of the space $Z^2$ is redundant. It can be derived from the number of indices and is therefore dropped for the sake of brevity.
4 Equational Specification

An intuitive and general way of specifying programs in the \(\mathcal{Z}\)-polyhedral model is through a list of high level (mutually recursive) equations.

Consider the red-black SOR [26] for the iterative computation of partial differential equations. Iterations in the \((i, j)\)-plane are divided into “red” points and “black” points, similar to the layout of squares in a chess board. First, black points (at even \(i + j\)) are computed using the four neighbouring red points (at odd \(i + j\)), then the red points are computed using its four neighbouring black points. These two phases are repeated until convergence. Introducing an additional dimension, \(k\) to denote the iterative application of the two phases, we get the following equation

\[
C_{i,j,k} = \begin{cases} 
\frac{1}{4}(C_{i-1,j,k-1} + C_{i+1,j,k-1} + C_{i,j-1,k-1} + C_{i,j+1,k-1}) & \text{// black update} \\
\frac{1}{4}(C_{i-1,j,k} + C_{i+1,j,k} + C_{i,j-1,k} + C_{i,j+1,k}) & \text{// red update}
\end{cases}
\]

This equation, with appropriate syntactic sugaring, is our preferred program in the \(\mathcal{Z}\)-polyhedral model. Here, \(C\) and the two branches of the equation are defined over \(\mathcal{Z}\)-polyhedral domains. A \(\mathcal{Z}\)-polyhedral domain is a union of \(\mathcal{Z}\)-polyhedra.

In general, the input for our scheduling analysis is a finite list of equations of the form

\[
V = \left\{ \cdots \; \mathcal{D}_{V,i} \; \mathcal{D}_{V,j} \; \mathcal{D}_{V,k} \; \cdots \right\}
\]

(2)

where \(V\) and \(U\) are variables declared over the \(\mathcal{Z}\)-polyhedral domains \(\mathcal{D}_V\) and \(\mathcal{D}_U\) respectively, \(\mathcal{D}_{V,i}\) is the \(\mathcal{Z}\)-polyhedral domain of the corresponding branch of the equation and \(\mathcal{D}_p\) is an arbitrary, atomic, iteration-wise, single-valued function that takes a single time-step to evaluate. The affine lattice function \((Lz + l \rightarrow Rz + r)\) is a dependence such that the value of the (sub)expression, \(U.(Lz + l \rightarrow Rz + r)\) at \(Lz + l\) equals the value of \(U\) at \(Rz + r\). The domains of different branches of an equation are disjoint and satisfy \(\bigcup \mathcal{D}_{V,i} = \mathcal{D}_V\) to ensure that any variable is not under- or over-defined. Variables that are not defined by an equation are treated as input. These equations can be obtained from the more general equational language presented in [9] through a transformation based on the closure properties of \(\mathcal{Z}\)-polyhedral domains, called normalization.

Parameterized equational specifications in the \(\mathcal{Z}\)-polyhedral model are based on parameterized \(\mathcal{Z}\)-polyhedra. An instance of a parameterized specification is called a program instance. Every program instance in a parameterized specification is independent, thus, all dependences should map consumer iterations to producer iterations within the same program instance.

Our presentation of the equational specification is based on the ALPAK language [18, 13] and the MMALPHA framework for manipulating ALPAK programs, which relies on a library for manipulating polyhedra [25].

4.1 Basic Reduced Dependency Graph

A directed multi-graph called the reduced dependence graph, RDG, precisely describes the dependences between iterations of variables. It is defined as follows
• For every variable in the specification, there is a vertex in the RDG labeled by its name and annotated by its domain. We will refer to vertices and variables interchangeably.

• For every dependence of the variable $V$ on $U$, there is an edge from $V$ to $U$. It is annotated by the corresponding dependence function. We will refer to edges and dependences interchangeably.

At a finer granularity, every branch of an equation is associated to dependences between computations. Thus, a precise analysis would dictate that dependences be expressed separately for every branch. Again, for reasons of precision, we will express dependences of a variable separately for every element in the $Z$-polyhedral domain of the corresponding branch of its equation. To enable these, we will replace a variable by a set of new variables as elaborated below.

In (2), let $D_{V,i}$ be written as a disjoint union of $Z$-polyhedra given by $\bigcup_j Z_j$. The variable $V$ in the domain $Z_j$ is replaced by a new variable, say $X_j$. Similarly, let $U$ be replaced by new variables given as $Y_k$. The dependence of $V$ in $D_{V,i}$ on $U$ is replaced by dependences from all $X_j$ on all $Y_k$. An edge from $X_j$ to $Y_k$ may be omitted if there are no iterations in $X_j$ that map to $Y_k$ (mathematically, if the preimage of $Y_k$ by the dependence function does not intersect with $X_j$).

A naive construction following these rules results in the basic reduced dependence graph. Figure 3a gives the basic RDG for example 1 which can be written as the following equation for $i \geq 1$.

$$A = \{2i|0 \leq 2i \leq n\} \quad A.(2i \rightarrow i) \quad \text{(denoted by $X$)}$$

$$\{2i-1|0 \leq 2i - 1 \leq n\} \quad 0 \quad \text{(denoted by $Y$)}$$

Next, we will study a refinement on this RDG.

### 4.2 Refined Reduced Dependence Graph

In the RDG for the generic equation given in (2), let $X$ be a variable derived from $V$ and defined on $Z_X \in D_{V,i}$, and let $Y$ be a variable derived from $U$ defined on $Z_Y \in D_U$ where $Z_X$ and $Z_Y$ are given as follows

$$Z_X = \{L_Xz_X + l_X|z_X \in P_X^c\}$$

$$Z_Y = \{L_Yz_Y + l_Y|z_Y \in P_Y^c\}$$

A dependence of the form $(Lz + l \rightarrow Rz + r)$ is directed from $X$ to $Y$. $X$ at $(Lz + l) \in Z_X$ cannot be evaluated before $Y$ at $(Rz + r) \in Z_Y$. The affine lattice $\{Lz + l|z \in Z^n\}$ may contain
points that do not lie in the affine lattice \( \{ L_X z_X + l_X | z_X \in \mathbb{Z}^{n_X} \} \). Similarly, the affine lattice \( \{ Rz + r | z \in \mathbb{Z}^n \} \) may contain points that do not lie in the affine lattice \( \{ L_Y z_Y + l_Y | z_Y \in \mathbb{Z}^{n_Y} \} \). As a result, the dependence may be specified on a finer lattice than necessary and may safely be replaced by dependence of the form \( (L'z' + l' \rightarrow R'z' + r') \) where

\[
L' = L_X S, l' = L_X s + l_X \\
R' = L_Y S', r' = L_Y s' + l_Y
\]

(3)

where \( S \) and \( S' \) are matrices and \( s \) and \( s' \) are integer vectors. The refined RDG is a refinement of the basic RDG where every dependence has been replaced by a dependence satisfying (3). Figure 3b gives the refined RDG for example 1.

5 The Scheduling Problem

Here, we will present the precedence imposed by dependences and then formulate an integer linear program to obtain valid schedules.

5.1 Causality Constraints

Dependences between the different iterations of variables impose an ordering on their evaluation. A valid schedule of the evaluation of these iterations is the assignment of an execution time to each computation so that precedence (causality) constraints are satisfied.

Let \( X \) and \( Y \) be two variables in the refined RDG defined on \( \{ L_X z_X + l_X | z_X \in \mathcal{P}_X \} \) and \( \{ L_Y z_Y + l_Y | z_Y \in \mathcal{P}_Y \} \) respectively. We seek to find schedules on \( X \) and \( Y \) of the following form

\[
\lambda'_X(z_X) = (L_X z_X + l_X \rightarrow \lambda_X(z_X)) \\
\lambda'_Y(z_Y) = (L_Y z_Y + l_Y \rightarrow \lambda_Y(z_Y))
\]

(4)

where \( \lambda_X \) and \( \lambda_Y \) are affine functions on \( z_X \) and \( z_Y \) respectively. Our motivation for such schedules is that all vectors and matrices comprise of integer scalars. If we seek schedules of the form \( \lambda'(z') \) where \( \lambda' \) is an affine function and \( z' \) is an iteration in the domain of a variable, then we may potentially assign execution times to “holes” or computations that do not exist. In general, we seek multidimensional schedules in the form of affine functions on coordinate indices.

We will now formulate causality constraints using the refined RDG. Consider dependences from \( X \) to \( Y \). All such dependences can be written as

\[
(L_X(Sz + s) + l_X \rightarrow L_Y(S'z + s') + l_Y)
\]

where \( S \) and \( S' \) are matrices and \( s \) and \( s' \) are vectors. The execution time for \( Y \) at \( L_Y(S'z + s') + l_Y \) should precede the execution time for \( X \) at \( L_X(Sz + s) + l_X \). With the nature of the schedules presented in (4), our causality constraint becomes

\[
\lambda_X(Sz + s) - \lambda_Y(S'z + s') \geq 1
\]

(5)
5.2 ILP Formulation

Here, we extract ILP (integer linear programming) constraints from causality constraints, as well as non-negativity of schedule. Then, we complete the ILP formulation with an objective function. Since our aim is using the PIP (Parameter Integer Programming) solver [4], the ILP formulation will be suitable form for the solver. We also show how a multidimensional schedule can be obtained in this model.

First, consider the non-negativity of schedule and therefore of the affine function λ. For each variable X, we want to impose the following condition:

∀z ∈ P_X, λ_X(z_X) ≥ 0

By affine form of Farkas Lemma, this condition holds when λ_X(z) is a non-negative affine combination of the constraints C of P_X, i.e.

λ_X(z) = λ_X,0 + \sum_{k=1}^{b_X} λ_{X,k}(a^{T}_{X,k}z + \alpha_{X,k})

where λ_{X,i} ≥ 0 for all i = 0, . . . , b and a^{T}_{X,k}z + \alpha_{X,k} ≥ 0 is the k-th constraint of C. From now on, this is a prototype of affine schedule functions.

Now, consider the causality constraint presented in (5) for the dependence from X to Y.

λ_X,0 + \sum_{k=1}^{b_X} λ_{X,k}(a^{T}_{X,k}(Sz + s) + \alpha_{X,k}) - λ_{Y,0} - \sum_{k=1}^{b_Y} λ_{Y,k}(a^{T}_{Y,k}(S'z + s') + \alpha_{Y,k}) - 1 ≥ 0

where Sz + s ∈ P_X and S'z + s' ∈ P_Y. Equivalently, we may say z ∈ P'_{X} ∩ P'_{Y} where P'_{X} and P'_{Y} are the preimage of P_X by (z → Sz + s) and P_Y by (z → S'z + s') respectively.

Now, first we will illustrate how to formulate the ILP constraints with the help of an example. Then, we will introduce an objective function for minimizing latency.

Consider Example 1 and its refined RDG given in figure 3b. By the non-negativity constraints, the affine functions λ_X and λ_Y will be of the form

λ_X = λ_{X,0} + λ_{X,1}(2i - 1) + λ_{X,2}(N - 2i)
λ_Y = λ_{Y,0} + λ_{Y,1}(2i - 2) + λ_{Y,2}(N - 2i + 1)

For the edge (4i - 2 → 2i - 1) from X to Y, the causality constraint is

λ_{X,0} + λ_{X,1}(4i - 3) + λ_{X,2}(N - 4i + 2) - λ_{Y,0} - λ_{Y,1}(2i - 1) - λ_{Y,2}(N - 2i - 1) ≥ 1

Similarly, an ILP constraint for the edge (4i → 2i) translates into the following condition

λ_{X,0} + λ_{X,1}2i + λ_{X,2}(N - 4i) - λ_{X,0} - λ_{X,1}i - λ_{X,2}(N - 2i) ≥ 1

where all the unknowns are non-negative. Since Y is assigned to a constant, one possibility is λ_{Y,0} = λ_{Y,1} = λ_{Y,2} = 0. In this case, Equation (6) can be simplified to the following form

(λ_{X,0} - λ_{X,1} + λ_{X,2} - 1) + (2λ_{X,1} - λ_{X,2})(2i - 1) + (λ_{X,2})(N - 2i) ≥ 0
Similarly, Equation (7) also simplifies to
\[(\lambda_{X_1} - \lambda_{X_2} - 1) + (\lambda_{X_1} - \lambda_{X_2})(2i - 1) \geq 0\]

Now, we have the following inequalities
\[
\begin{align*}
\lambda_{X_0} - \lambda_{X_1} + \lambda_{X_2} - 1 & \geq 0 \\
2\lambda_{X_1} - \lambda_{X_2} & \geq 0 \\
\lambda_{X_0} & \geq 0 \\
\lambda_{X_1} - \lambda_{X_2} - 1 & \geq 0 \\
\lambda_{X_1} - \lambda_{X_2} & \geq 0
\end{align*}
\]

(8)

All these steps for deriving ILP constraints can be performed automatically and these inequalities can be systematically solved by standard ILP solvers.

Now, we present an objective function when all domains are bounded. In this case, there exists an affine expression \(\mathcal{L}\) of the program parameters such that \(\mathcal{L} - \lambda_X(z) \geq 0\) for all \(z \in \mathcal{P}_X\) if there exists an affine function \(\lambda_X\). So, it does not restrict the space of valid affine function \(\lambda_X\). We want to minimize the total latency by minimizing \(\mathcal{L}\). In order to use the PIP solver, for each variable \(X\) we first add \(\mathcal{L} - \lambda_X(z) \geq 0\) to the constraints, and the unknown variables in \(\mathcal{L}\) are placed into the outermost dimensions because PIP solver gives the lexicographic minimum of a given parameterized polyhedron.

Let us continue Example 1. For the minimum latency affine schedule, we add the following constraints from \(\mathcal{L}(= \mu_0 N + \mu_1) - \lambda_X(z)\). Solving, we get
\[
\mu_0 N + \mu_1 - \lambda_{X_0} - \lambda_{X_1}(2i - 1) - \lambda_{X_1}(N - 2i) \geq 0
\]
or \((\mu_0 - \lambda_{X_0})(N - 2i) + (\mu_0 - \lambda_{X_1})(2i - 1) + (\mu_0 + \mu_1 - \lambda_{X_0}) \geq 0\)

which implies the following
\[
\begin{align*}
\mu_0 - \lambda_{X_0} & \geq 0 \\
\mu_0 - \lambda_{X_1} & \geq 0 \\
\mu_0 + \mu_1 - \lambda_{X_0} & \geq 0
\end{align*}
\]

(9)

Note that for the sake of simplicity, we do not consider the variable \(Y\) that is constant on all its iterations. In fact, Equation (8) and (9) defines a polyhedron. Since we put \(\mu_0\) into the first dimension index, the lexicographic minimum of this polyhedron will provide minimum latency schedules for each variable. Finally, we will get the following schedules for \(X\) and \(Y\)
\[
\begin{align*}
\lambda'_X & : 2i \rightarrow i \\
\lambda'_Y & : 2i + 1 \rightarrow 0
\end{align*}
\]

Now, consider multidimensional schedules in this model. The basic idea is the same as that in Polyhedral model. Thus, rather than presenting technical details, we just provide a precise and intuitive (maybe inefficient) formulation for multidimensional schedules. The basic idea of the following ILP formulation is satisfying as many dependences as possible and
the theory justifying this formulation is given by Feautrier [7].

\[
\max \sum_{e \in E} x_e \\
\text{subject to } 0 \leq x_e \leq 1 \\
\lambda_X(Sz + s) - \lambda_Y(S'z + s') - 1 \geq x_e \\
\lambda_X(z) \geq 0
\]

A new variable \(x_e\) for each \(e \in E\) is introduced. When \(x_e = 1\), the dependence associated to edge \(e\) will be satisfied. The objective function maximizes the number of the edges that are satisfied. The multidimensional time can be obtained in this model by the same way in the polyhedral model.

The purpose of this section was to present the transformation of causality constraints into ILP constraints precisely and the illustration of this step with the help of an example. For technical details on Farkas scheduling algorithm, please refer to [6] by Feautrier.

6 Related Work

The scheduling problem on recurrence equations with uniform (constant-sized) dependences was originally presented by Karp et. al. [11]. A similar problem was posed by Lamport [12] for programs with uniform dependences. Shang and Fortes [24] and Lisper [17] presented optimal linear schedules for uniform dependence algorithms.

Rao [23] first presented affine by variable schedules for uniform dependences (Darte et. al [2] showed that these results could have been interpreted from [11]). The first result of scheduling programs with affine dependences was solved by Rajopadhye and Fujimoto [21], and independently by Quinton and Van Dongen [20]. These results were generalized to variable dependent schedules by Mauras et. al. [19]. Feautrier and Darte et. al independently presented the optimal solution to the affine scheduling problem (by variable) [6, 3]. Feautrier also provided the extension to multidimensional time [7]. The scheduling problem was studied along with the objective for minimizing communication by Lim at. al. [16].

In this paper, we have extended these techniques to a class of programs that is strictly more general than those considered previously. Moreover, the schedules that we construct can be directly used to perform appropriate program transformations.

7 Conclusions and Future Work

The polyhedral model has been widely studied for the automatic parallelization of loop programs. However, it is limited in expressivity. It was recently extended to \(Z\)-polyhedral domains [9]. In this paper, we presented the scheduling analysis for the \(Z\)-polyhedral model, a strict generalization of the polyhedral model, to obtain multidimensional schedules with minimum latency. Our schedules are of the form \(X'(z) = (Lz + l \rightarrow \lambda(z))\) where \(\{Lz + l|z \in \mathbb{Z}^n\}\) is the lattice corresponding to the \(Z\)-polyhedron and \(\lambda(z)\) is the affine function (comprising of integer scalars) on the coordinates of this lattice. As a result, an important property of our ILP formulation is that it searches only in the space of functions that can subsequently be used to construct a space-time transformation of the program.
Our schedules express unbounded parallelism and thus cannot directly be realized in any parallel hardware. However, such parallelism detection is the crucial precursor to any resource constrained analysis.

Future work involves the derivation of parallel code from our high level equations. We also aim to implement these transformations into a compiler optimization framework.
