abstract  = {Parallel reduction, which summarizes a given dataset, e.g., the
total, average, and maximum, plays a crucial role in parallel programming.
This paper presents a new approach, reverse engineering, to automatically
discovering nontrivial parallel reductions in sequential programs. The body
of the sequential reduction loop is regarded as a black box, and its input-
output behaviors are sampled. If the behaviors correspond to a set of linear
polynomials over a semiring, a divide-and-conquer parallel reduction is
generated. Auxiliary reverse-engineering methods enable a long and nested
loop body to be decomposed, which makes our parallelization scheme
applicable to various types of reduction loops. This approach is not only
simple and efficient but also agnostic to the details of the input program.
Its potential is demonstrated through several use case scenarios. A proof-
of-concept implementation successfully inferred linear polynomials for
nearly all of the 74 benchmarks exhaustively collected from the literature.
These characteristics and experimental results demonstrate the promise of
the proposed approach, despite its inherent unsoundness.},

abstract    = {Many sequential loops are actually recurrences and can be  
parallelized across iterations as scans or reductions. Many efforts over the  
past 2+ decades have focused on parallelizing such loops by extracting and  
exploiting the hidden scan/reduction patterns. These approaches have largely  
been based on a heuristic search for closed-form composition of computations  
across loop iterations. While the search-based approaches are successful in  
parallelizing many recurrences, they have a large search overhead and need  
extensive program analysis. In this work, we propose a novel approach called  
sampling-and-reconstruction, which avoids the search for closed-form  
composition and has the potential to cover more recurrence loops. It is  
based on an observation that many recurrences can have a point-value  
representation. The loop iterations are divided across processors, and where  
the initial value(s) of the recurrence variable(s) are unknown, we execute  
with several chosen (sampling) initial values. Then, correct final result  
can be obtained by reconstructing the function from the outputs produced on  
the chosen initial values. Our approach is effective in parallelizing  
linear, rectified-linear, finite-state and multivariate recurrences, which  
cover all of the test cases in previous works. Our evaluation shows that our  
approach can parallelize a diverse set of sequential loops, including cases  
that cannot be parallelized by a state-of-the-art static parallelization  
tool, and achieves linear scalability across multiple cores.},

```

architectures from Recurrence Equations. A class of such equations (Recurrence Equations with Linear Dependencies) is defined and the problem of mapping such equations onto a two dimensional architecture is studied. We show that such a mapping is provided by means of a linear allocation and timing function. An important result is that under such a mapping the dependencies remain linear. After obtaining a two-dimensional architecture by applying such a mapping, a systolic array can be derived if the communication can be spatially and temporally localized. We show that a simple test consisting of finding the zeroes of a matrix is sufficient to determine whether this localization can be achieved by pipelining and give a construction that generates the array when such a pipelining is possible. The technique is illustrated by automatically deriving a well known systolic array for factoring a band matrix into lower and upper triangular factors.},

abstract = {The authors present new scheduling techniques for systems of affine recurrence equations. They show that it is possible to extend earlier results on affine scheduling to the case when each variable of the system is scheduled independently of the others by an affine timing-function. This new technique makes it possible to analyze systems of recurrence equations with variables in different index spaces, and multi-step systolic algorithms. This theory applies directly to many problems, such as dynamic programming, LU decomposition, and 2-D convolution, and it avoids in particular preliminary heuristic rewriting of the equations.},
