Magicians protect their secrets not because the secrets are large and important, but because they are so small and trivial. The wonderful effects created on stage are often the result of a secret so absurd that the magician would be embarrassed to admit that that was how it was done.

Christopher Priest, The Prestige

**Why Virtualization**

Sands often have multiple, dedicated servers: e-mail, FTP, e-commerce, web, etc.

- **Load:** Maybe one machine cannot handle all that load
- **Reliability:** Management does not trust the OS to run 24 x 7 without failures
- By putting one server on a separate computer, if one of the server crashes?
  - At least the other ones are not affected
- If someone breaks into the web server, at least sensitive e-mails are still protected
  - **Sandboxing**
But ...

- While this approach achieves **isolation** and fault tolerance
  - This solution is **expensive** and **hard to manage** because so many machines are also involved

- Other reasons for having separate machines?
  - Organizations depend on more than one OS for their daily operations
    - Web server on Linux, mail server on Windows, e-commerce server on OS X, other services on various flavors of UNIX

What can be done?

- A possible (and popular) solution is to use virtual machine technology

- This sounds very hip and modern
  - But the idea is old ... dating back to the 1960s
  - Even so, the way we use it today is definitely new
Main idea

- **VMM** (Virtual Machine Monitor) creates the *illusion* of multiple (virtual) machines on the same physical hardware
  - VMM is also known as a **hypervisor**
    - We will look at type 1 hypervisors (bare metal) and type 2 hypervisors (use services and abstractions offered by an underlying OS)

- **Virtualization** allows a single computer to host multiple virtual machines
  - Each potentially running a different OS

Failure in one of the virtual machines does not bring down any others

- Different servers run on different virtual machines
  - Maintains **partial-failure** model at a lower cost with easier maintainability

- Also, we can run different OS on the same hardware
  - Benefit from virtual machine isolation in the face of attacks
  - Plus enjoy other good stuff: savings, real estate, etc.
But isn’t consolidating servers like this putting all your eggs in the same basket?

- If the server running the virtual machines fails?
  - The result is even more catastrophic than the crashing of a single dedicated server

Why virtualization works

- Service outages are due not to faulty hardware, but due to poor software, emphatically including OSes
  - Ill-designed, unreliable, buggy, and poorly configured software
Why virtualization works

- The only software running in the *highest privilege* is the hypervisor
- Hypervisor has 2 orders of magnitude fewer lines of code than a full operating system
  - Has 2 orders of magnitude fewer bugs
- A hypervisor is simpler than an OS because it *does only one thing*
  - Emulate copies of the bare metal (most commonly the Intel x86 architecture)

Advantages to running software in VMs besides strong isolation

- Fewer physical machines
  - Saves money on hardware and electricity
  - Takes up less rack space
- For companies such as Amazon or Microsoft
  - Reducing physical demands on data centers represents huge cost savings
  - Companies frequently locate their data centers in the middle of nowhere
    - Just to be close to hydroelectric dams (and cheap energy)

Checkpointing and migration

- For load balancing across multiple servers
- Easier with VMs than migrating processes running on a normal OS
- Why?
  - In the bare metal case, a fair amount of critical state information about each process is kept in OS tables
  - When migrating a VM, all that has to be moved are the memory and disk images
    - All the OS tables move as well
Other uses of virtual machines

- Run legacy applications
- Software development: Test software on myriad OSes
  - No need to get a dozen computers and install a dozen OS
    - Just install a dozen VMs
    - Of course, you could have partitioned your hard-disk and installed a different OS but that is more difficult
      - Standard PCs allow only four primary disk-partitions, no matter how big the disk is
      - Although a multiboot program can be installed in the boot-block, it would be necessary to reboot computer to work on a new OS
  - With VMs, all of them run at once, since they are just glorified processes

Key idea of the cloud is straightforward

- Outsource computation/storage needs to a well managed data center
- Pay for use of resources, but at least you will not have to worry about physical machines, power, cooling, and maintenance
A BRIEF HISTORY OF VIRTUALIZATION

1960s

- Early 1960s IBM experimented with not just one, but two independently developed hypervisors
  - SIMMON and CP-40

- CP-40 was a research project that was reimplemented as CP-67 to form the control program of CP/CMS a virtual machine OS for IBM/360

Those who do not remember the past are condemned to repeat it.
George Santayana
1970s

- In 1974, Gerald Popek and Robert Goldberg published a seminal paper*.
  - Listed what conditions a computer architecture should satisfy to support virtualization efficiently.
- Famously, the well-known x86 architecture that originated in the 1970s did not meet this for decades.
- 1970s were very productive, seeing the birth of UNIX, Ethernet, Cray-1, Microsoft, and Apple.

The path to VMware

- Researchers at Stanford developed a new hypervisor called Disco.
  - Went on to found VMware a virtualization giant.
    - Offers type-1 and type-2 hypervisors.
- VMware introduced its first virtualization solution for x86 in 1999.
- Other products followed in its wake:
  - Xen, KVM, VirtualBox, Hyper-V, Parallels.
**Requirements for Virtualization**

---

**Trap: Revisiting the concept**

- A **trap** is a synchronous interrupt caused by an exceptional condition
  - E.g.: divide by zero, invalid memory access, etc.

- Usually results in a **switch to kernel mode**
  - The kernel performs some action before returning control to the originating process
Requirements for virtualization

- Virtual machines must act just like the real McCoy
  - Must be possible to boot them and install arbitrary OS on them
    - Just as on the real hardware
- Task of the hypervisor is to provide this illusion and to do it efficiently

Hypervisors should score well on

- Safety
  - Hypervisor should have full control of the virtualized resources
- Fidelity
  - Behavior of program on a virtual machine should be identical to the same program running on bare hardware
- Efficiency
  - Much of the code in the virtual machine should run without intervention from the hypervisor
Safety

- Consider each instruction in turn in an interpreter (such as Bochs) and perform exactly what is needed
  - May execute some instructions as is, but other instructions must be simulated
- We cannot allow the guest OS to disable interrupts for the entire machine or modify page-table mappings
  - Trick is to make the guest OS believe that it has
- Interpreter may be safe, even hi-fi, but performance is abysmal
  - So, VMMs try to execute most code directly

Fidelity

- **Privileged** instructions
  - Trap if the processor is in user mode and do not trap if it is in system/kernel mode (supervisor mode)
- Control **sensitive** instructions
  - Attempt to change configuration of system resources
- Behavior **sensitive** instructions
  - Whose behavior or result depends on the configuration of resources (content of relocation register or processor's mode)
Fidelity and the x86

Virtualization has long been a problem on x86
- Defects in 386 carried forward into new CPUs for 20 years in the name of backward compatibility

- If you do something in user mode that you should not
  - The hardware should trap!
  - IBM/370 had this property, Intel's 386 did not

- Several sensitive 386 instructions were ignored if executed in user mode
  - Or executed with a different behavior
  - E.g., POPF instruction replaces flags register which changes the bit that enables/disables interrupts
    - In user-mode this bit was simply not changed

- Also, some instructions could read sensitive state in user mode without causing a trap
### Fidelity and the x86

- The x86 contained 18 sensitive, unprivileged instructions
- Sensitive register instructions
  - Read or change sensitive registers or memory locations such as a clock register or interrupt registers
- Protection system instructions
  - Reference the storage protection system, memory or address relocation system

### Problem solved in 2005

- When Intel and AMD introduced virtualization in their CPUs
  - Intel CPUs: It is called VT (Virtualization Technology)
  - AMD CPUs: SVM (Secure Virtual Machine)
- Create containers in which VMs can be run
- When a guest OS is started in a container, continues to run until it causes an exception and traps to the hypervisor
  - For e.g., by executing an I/O instruction
- Set of operations that trap is controlled by a **hardware bit map** set by hypervisor
  - Classical **trap-and-emulate** approach becomes possible
What happened before that?

- Hypervisors before 2005 did not really run the original guest OS
  - Rewrote part of the code on the fly
    - To replace problematic instructions with safe code sequences that emulated original instruction
    - Replace instructions that are sensitive but not privileged
    - Binary Translation

Full virtualization

- Trap all instructions
- Fully simulate entire computer
- Trade-off: High overhead
- Benefit: Can virtualize any OS
Paravirtualization [1/2]

- Never aims to present a virtual machine that looks just like the actual underlying hardware
- Present **machine-line software interface** that explicitly exposes that it is a virtualized environment
  - Offers a set of **hypercalls** that allow the guest to send explicit requests to the hypervisor
    - Similar to how a system call offers kernel services to applications
- **DRAWBACK**: Guest OS has to be aware of the virtual machine API

Paravirtualization [2/2]

- Guests use hypercalls for privileged, sensitive operations like updating page tables
  - But they do it in cooperation with the hypervisor
  - Overall system can be simpler and faster
- Paravirtualization was offered by IBM since 1972
- Idea was revived by Denali (2002) and Xen (2003) hypervisors
Not all virtualization attempt to trick the guest into believing it has entire system

- Sometimes the aim is to allow a process to run that was run on different OS and/or architecture
  - **Process-level virtualization**

- **Examples:**
  - WINE Compatibility layer allows Windows applications to run on POSIX-compliant systems like Linux, BSD, OS X
  - Process-level version of the QEMU emulator allows applications for one architecture to run on another

**Type-1 and Type-2 Hypervisors**
Terms

- **Guest Operating System**
  - The OS running on top of the hypervisor

- **Host Operating System**
  - For a type 2 hypervisor: the OS that runs on the hardware

- **Safe executions**
  - Execute the machine’s instruction set in a safe manner
  - Guest OSes may change or mess up its own page tables ... but not those of others

Type 1 hypervisor

- Only program running in the most privileged mode
- Support multiple copies of the actual hardware
  - Virtual machines
  - Similar to processes a normal OS would run
Location of Type-1 hypervisor

Control Domain in the Type-1 hypervisor: Also known as Dom0

- Is a VM like the guest VMs, with two functional differences
  - Has the ability to talk to the hypervisor to instruct it to start and stop guest VMs
  - By default, contains the device drivers needed to address the hardware
Type 2 hypervisor

- Also referred to as **hosted hypervisor**
- Relies on a host OS, say Windows or Linux, to allocate and schedule resources
- Still pretends to be a full computer with a CPU and other devices

Type 2: Running Guest OS

- When it starts for the first time, acts like a newly booted computer
  - Expects to find a DVD, USB drive or CD-ROM containing an OS
    - The drive could be a virtual device
    - Store the image as an ISO file (optical disk image ISO 9660 file system) on the hard drive and have hypervisor pretend its reading from proper DVD drive
- Hypervisor installs the OS to its virtual disk (just a file) by running installation that it found on DVD
- Once guest OS is installed on virtual disk, it can be booted and run
